1) Detail Dataset

Details

- This dataset is used for **emotion classification from text**.
- Each row represents one text sample and its target emotion label.
- In this notebook, label mapping is: `0: Sadness, 1: Joy, 2: Love, 3: Anger, 4: Fear, 5: Surprise`.

```
# Data structure evidence: first rows + dataframe info + dtypes + null

```

Written Interpretation (for report)

Based on the `df.head()` output, the dataset contains text samples and their encoded emotion labels. The current working file is `data/text.xlsx`, and it includes three columns: `Unnamed: 0`, `text`, and `label`. From `df.info()`, the dataset has **416,809 rows** and **3 columns**, with data types: two numerical (`int64`) columns (`Unnamed: 0`, `label`) and one object/categorical text column (`text`). From the null-value analysis (overall, object/categorical, and numerical subsets), there are **no missing values** in any column (all null counts are 0, i.e., 0.00%). This indicates good structural integrity for model training without mandatory imputation. The data dictionary confirms each feature role: `text` is the input feature, `label` is the target class (0: Sadness, 1: Joy, 2: Love, 3: Anger, 4: Fear, 5: Surprise), and `Unnamed: 0` is an index-like identifier from the source export. Overall, the dataset is clean, fully populated, and ready for preprocessing and supervised emotion classification modeling.

2. Exploratory Data Analysis (EDA)

This section analyzes the dataset using summary statistics and visualizations. For each method, interpretation is provided to explain why it was used and what the results indicate.

Screenshot note for report submission: include screenshots of the generated charts and the printed tables below in your final document.

```
# EDA base table
import matplotlib.pyplot as plt
import seaborn as sns
import numpy as np
import pandas as pd

eda_df = dataset.copy()
eda_df['text'] = eda_df['text'].astype(str)
eda_df['text_length'] = eda_df['text'].str.len()
eda_df['word_count'] = eda_df['text'].str.split().str.len()
```

```
label_map = {0: 'Sadness', 1: 'Joy', 2: 'Love', 3: 'Anger', 4: 'Fear',
5: 'Surprise'}
eda_df['label_name'] = eda_df['label'].map(label_map)
eda_df.head()
```

```

Methodology & Interpretation — Numerical Summary

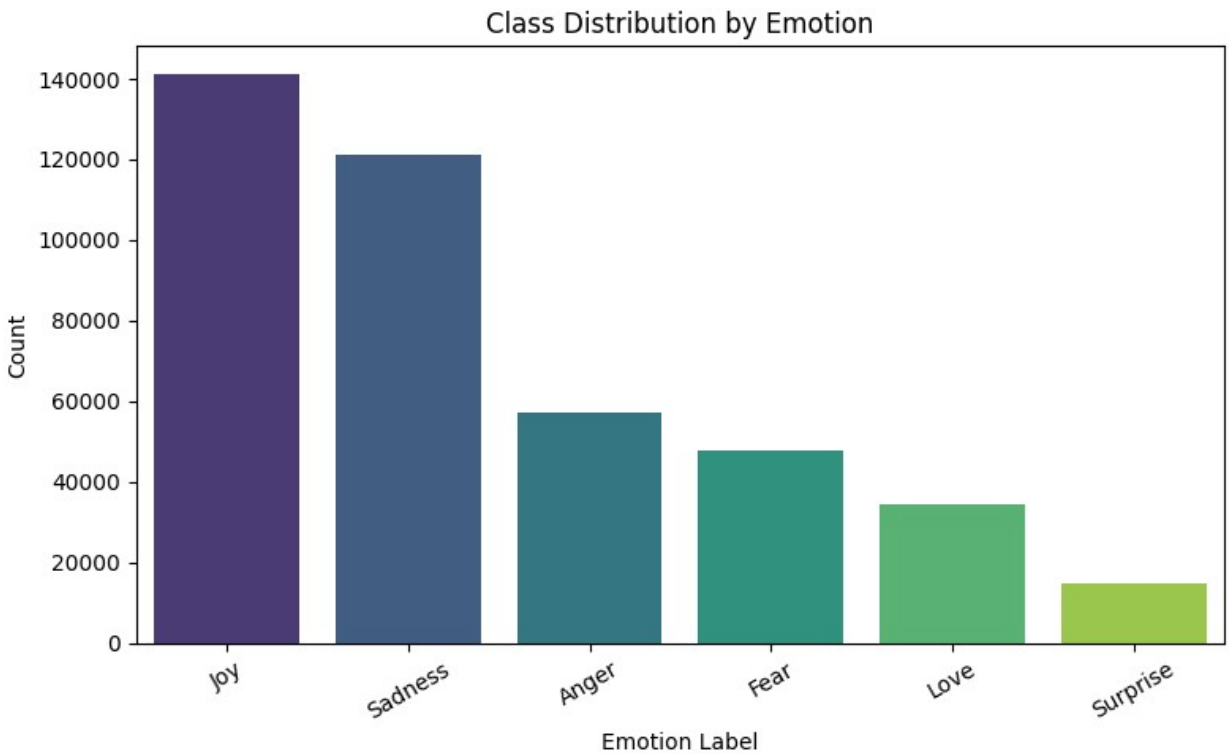
- **Why this method?** Mean, median, and standard deviation were used to quantify central tendency and spread of text size features (`text_length`, `word_count`).
- **What is it saying?** The summary shows the typical message size and how much variation exists, both overall and per emotion class. Differences between classes indicate that some emotions may be expressed with shorter or longer texts, which can help models discriminate classes.

```python
# Class distribution
class_counts = eda_df['label_name'].value_counts()
class_perc = (class_counts / len(eda_df) * 100).round(2)

plot_df =
class_counts.rename_axis('label_name').reset_index(name='count')

plt.figure(figsize=(8, 5))
sns.barplot(data=plot_df, x='label_name', y='count', hue='label_name',
palette='viridis', legend=False)
plt.title('Class Distribution by Emotion')
plt.xlabel('Emotion Label')
plt.ylabel('Count')
plt.xticks(rotation=30)
plt.tight_layout()
plt.savefig(f'{FIGURES_DIR}/class_distribution.png', dpi=300,
bbox_inches='tight')
plt.show()

print('Class Percentage Distribution (%):')
display(class_perc.rename('percentage').to_frame())
```



```
Class Percentage Distribution (%):

            percentage
label_name
Joy              33.84
Sadness          29.07
Anger            13.75
Fear             11.45
Love              8.29
Surprise          3.59
```

Methodology & Interpretation — Class Distribution Bar Chart

- **Why this method?** A bar chart is used to compare class frequencies clearly across discrete emotion categories.
- **What is it saying?** The chart and percentages reveal class imbalance (some emotions occur much more often than others). This suggests evaluation should include precision/recall/F1 and motivates balancing strategies before training.

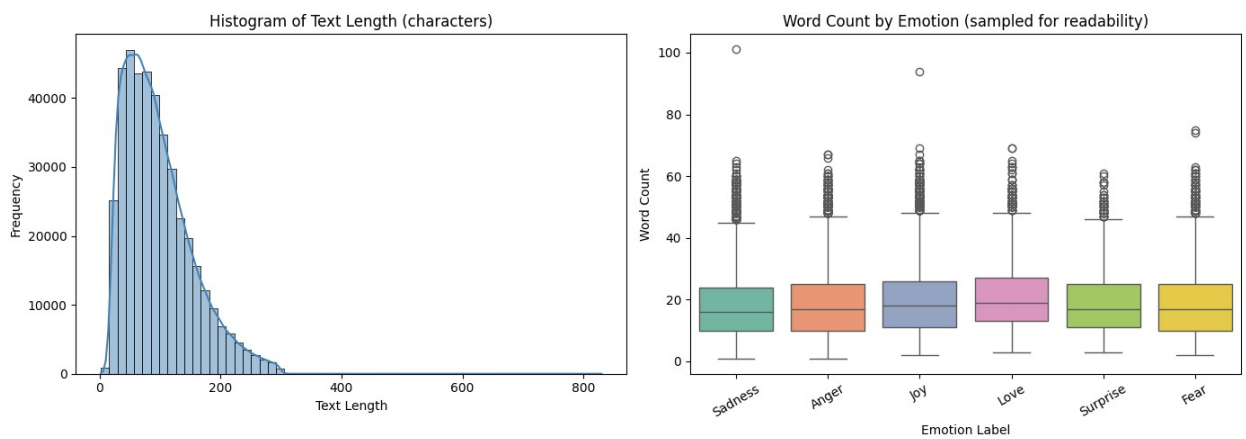
```
# Distribution of text size features
fig, axes = plt.subplots(1, 2, figsize=(14, 5))

sns.histplot(eda_df['text_length'], bins=60, kde=True, ax=axes[0],
color='steelblue')
axes[0].set_title('Histogram of Text Length (characters)')
axes[0].set_xlabel('Text Length')
```

```
axes[0].set_ylabel('Frequency')

sampled_df = eda_df.sample(min(50000, len(eda_df)), random_state=42)
sns.boxplot(data=sampled_df, x='label_name', y='word_count',
hue='label_name', ax=axes[1], palette='Set2', legend=False)
axes[1].set_title('Word Count by Emotion (sampled for readability)')
axes[1].set_xlabel('Emotion Label')
axes[1].set_ylabel('Word Count')
axes[1].tick_params(axis='x', rotation=30)

plt.tight_layout()
plt.savefig(f'{FIGURES_DIR}/text_length_wordcount.png', dpi=300,
bbox_inches='tight')
plt.show()
```



Methodology & Interpretation — Histogram + Boxplot

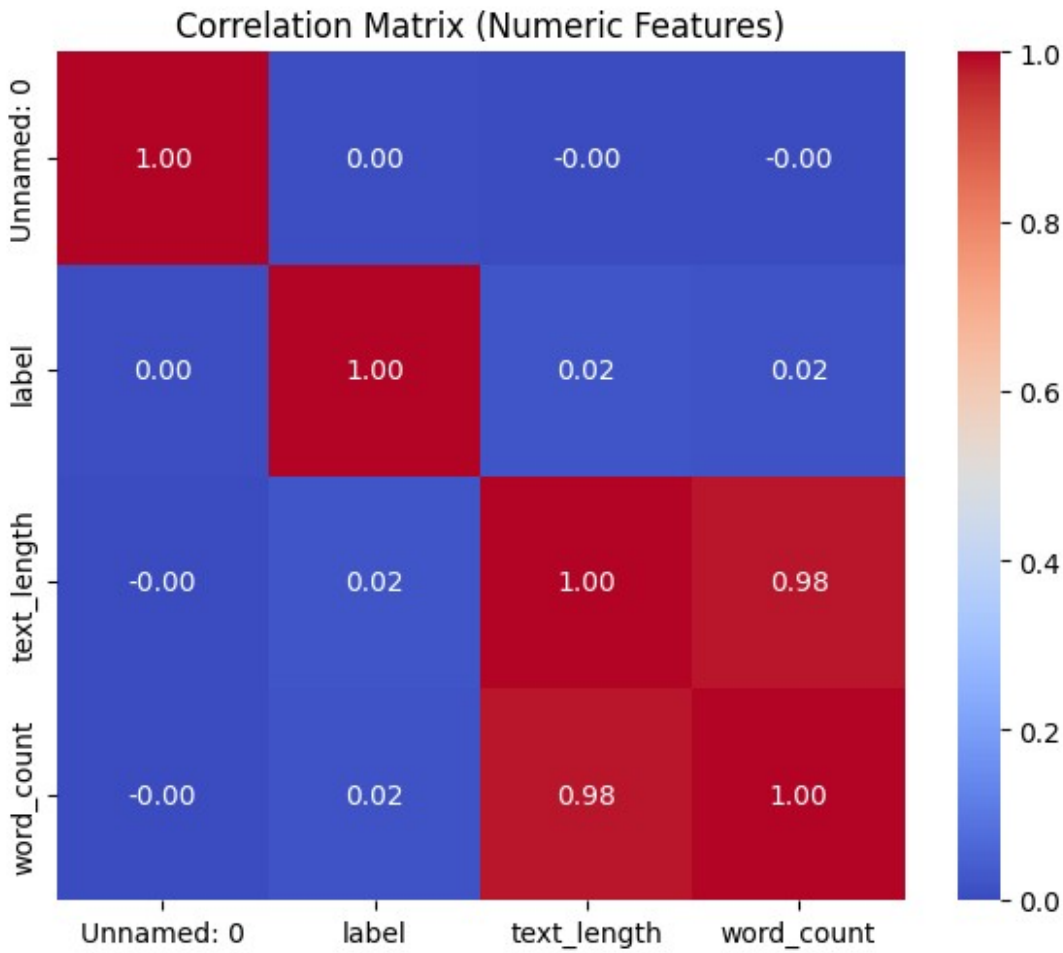
- **Why these methods?** A histogram checks global distribution shape, while a boxplot compares spread and outliers across labels.
- **What is it saying?** The histogram indicates whether text lengths are skewed or approximately centered; the boxplot highlights median differences and variability in word counts between emotions. These patterns support feature engineering decisions (padding length, truncation strategy, and model robustness to varying sequence size).

```
# Correlation matrix for numeric columns
corr_cols = ['Unnamed: 0', 'label', 'text_length', 'word_count']
corr_available = [col for col in corr_cols if col in eda_df.columns]
corr_matrix = eda_df[corr_available].corr(numeric_only=True)

plt.figure(figsize=(6, 5))
sns.heatmap(corr_matrix, annot=True, cmap='coolwarm', fmt='.2f',
square=True)
plt.title('Correlation Matrix (Numeric Features)')
plt.tight_layout()
plt.savefig(f'{FIGURES_DIR}/correlation_matrix.png', dpi=300,
bbox_inches='tight')
```

```
plt.show()

display(corr_matrix)
```



```

```

Methodology & Interpretation — Correlation Matrix

- **Why this method?** A correlation matrix helps quantify linear relationships among numerical features.
- **What is it saying?** Strong correlation between `text_length` and `word_count` is expected (longer texts contain more words), while weak correlation of `label` with these numeric features implies that class prediction depends more on semantic content than length alone.

Conclusion & Next Steps (Based on EDA)

Key findings from EDA

- The dataset is large and structurally clean (no null values).
- Emotion classes are imbalanced, so class-aware evaluation and balancing are necessary.
- Text-size features vary by class, but numeric length features alone are insufficient for strong emotion discrimination.
- Semantic text content is likely the primary signal for prediction.

Prediction goal

- Predict the emotion label (`Sadness`, `Joy`, `Love`, `Anger`, `Fear`, `Surprise`) from input text.

Planned model selection (and why)

- **BiLSTM (TensorFlow):** suitable for sequence data and contextual dependencies in text.
- **CNN for text:** captures local phrase patterns efficiently.
- **SVM with TF-IDF:** strong classical baseline for sparse text features.
- **XGBoost with TF-IDF:** non-linear baseline to compare with deep learning methods.

Link to EDA findings

- Because EDA shows class imbalance and variable text length, we will use stratified splitting/balancing, macro-averaged metrics (`precision`, `recall`, `F1`), and sequence padding for neural models.

Data Preprocessing

3.1 Class Balancing (Downsampling)

Why? The EDA revealed significant class imbalance — *Sadness* and *Joy* dominate while *Surprise* and *Love* are underrepresented. Training on imbalanced data would bias the classifier toward majority classes, inflating accuracy while underperforming on minority emotions.

Method chosen: Random downsampling to the size of the smallest class (~14,872 samples per class). This was preferred over SMOTE (synthetic oversampling) because SMOTE generates synthetic text features that may not carry meaningful semantic content, potentially introducing noise rather than signal in an NLP task.

Trade-off: Downsampling discards data from majority classes, but the remaining ~89k balanced samples are sufficient for robust training across all four model architectures.

```
#Balance class
def rebuild_dataframe(df, label_counts):
    min_count = min(label_counts)
    new_df = pd.DataFrame(columns=df.columns)

    for label in label_counts.index:
        label_data = df[df['label'] == label] ## Filter data for the
current label
        sampled_data = label_data.sample(n=min_count, random_state=42)
#random_state
        new_df = pd.concat([new_df, sampled_data])
```

```
    return new_df

balanced_dataset = rebuild_dataframe(dataset, label_counts)
print(balanced_dataset['label'].value_counts())
```

```
label

3.2 Text Cleaning Pipeline

The following cells apply an **eight-step NLP preprocessing pipeline** designed to normalise raw text into a clean format suitable for both deep learning (BiLSTM, CNN) and classical ML (SVM, XGBoost) models. The pipeline order is intentional and **fully aligned** with the production code in `app.py`:

1. **Lowercase** — eliminates case variance so "Happy" and "happy" are treated identically.
2. **Whitespace stripping** — removes leading/trailing spaces from data export artefacts.
3. **URL removal** — URLs carry no emotional signal and would add noise to TF-IDF features.
4. **Emoji removal** — emojis are converted to empty strings (run *before* special-char removal so emoji unicode is not partially stripped into garbage tokens).
5. **Special character removal** — keeps only `[a-z\s]`; digits and punctuation rarely contribute to emotion discrimination in this dataset.
6. **Chat word expansion** — maps 30 common abbreviations (e.g. "u" → "you", "lol" → "laugh out loud") to their full forms, improving vocabulary consistency.
7. **Stopword removal with negation preservation** — standard English stopwords are removed *except* negation words ("not", "never", "no", etc.) because negation flips emotional polarity (e.g., "not happy" vs. "happy").
8. **Lemmatisation** — reduces inflected forms to base form (e.g. "running" → "run") to shrink vocabulary size without losing meaning.

```python
#lower case
df['text'] = df['text'].str.lower()

# Remove extra white spaces
df['text'] = df['text'].str.strip()

# Remove URLs — aligned with train_pipeline.py / app.py
import re
df['text'] = df['text'].apply(lambda x: re.sub(r'http\S+|www\S+', '',
str(x)))

# Remove emojis — step 3 (aligned with train_pipeline.py / app.py
order)
import emoji

def remove_emojis(text):
    return emoji.replace_emoji(str(text), replace='')

df['text'] = df['text'].apply(remove_emojis)
df.head()
```

```
                                                     text label
244449  i made nico promise to run away screaming if i...     1
251513      i want to feel as carefree as i did back then     1

```

3.3 Mid-Pipeline Visualisation — Word Clouds

Word clouds are generated **after** stopword removal (step 7) but **before** lemmatisation (step 8) to verify that the cleaning pipeline has produced meaningful, class-discriminative vocabulary. If emotions share mostly identical top words, the features may be too generic; distinct keywords per class (e.g., "love", "afraid", "angry") confirm that the cleaned text retains emotional signal for downstream classification.

```python
import matplotlib.pyplot as plt
from wordcloud import WordCloud

label_map = {
    0: 'Sadness',
    1: 'Joy',
    2: 'Love',
    3: 'Anger',
    4: 'Fear',
    5: 'Surprise'
}

def generate_wordcloud(df, label):
    text = ' '.join(df[df['label'] == label]['text'].astype(str))
    wordcloud = WordCloud(width=400, height=200,
background_color='white').generate(text)
    plt.figure(figsize=(10, 5))
    plt.imshow(wordcloud, interpolation='bilinear')
    plt.axis('off')
    plt.title(f'Word Cloud for {label_map[label]}')

plt.savefig(f'{FIGURES_DIR}/wordcloud_{label_map[label].lower()}.png',
dpi=300, bbox_inches='tight')
    plt.show()

for label in label_map:
    generate_wordcloud(df, label)
```

```

3.4 Train / Validation / Test Split

The preprocessed data is split into three partitions using **stratified sampling** (`stratify=y`) to maintain equal class proportions across all splits:

Partition	Proportion	Purpose
Training set	64% of total	Model parameter learning
Validation set	16% of total	Hyperparameter tuning and early stopping
Test set	20% of total	Final unbiased performance evaluation

Why stratified? With six emotion classes now balanced at ~14,872 each, stratified splitting prevents any partition from accidentally over- or under-representing a class, which would distort evaluation metrics.

```
#train test split
from sklearn.model_selection import train_test_split
X = df['text']
y = df['label']
X_train, X_test, y_train, y_test = train_test_split(X, y,
test_size=0.2, random_state=42, stratify=y)
X_train_new, X_val, y_train_new, y_val = train_test_split(X_train,
y_train, test_size=0.2, random_state=0, stratify=y_train)

print("The shape of X_train is ", X_train_new.shape)
print("The shape of X_test is ", X_test.shape)
print("The shape of X_val is", X_val.shape)
print("The shape of y_train is", y_train_new.shape)
print("The shape of y_test is", y_test.shape)
print("The shape of y_val is", y_val.shape)
```

```
The shape of X_train is  (57492,)
The shape of X_test is  (17967,)
The shape of X_val is (14373,)
The shape of y_train is (57492,)
The shape of y_test is (17967,)
The shape of y_val is (14373,)
```

4.1 Tokenisation & Padding (for Deep Learning Models)

Why tokenise? BiLSTM and CNN require fixed-length integer sequences as input. The Keras `Tokenizer` maps each unique word to an integer index (vocabulary size capped at 60,000), and `pad_sequences` ensures all inputs have the same length so they can be batched as tensors.

- **OOV token (`<OOV>`)** — words unseen during training are mapped to this single token, preventing index errors at inference time.
- **Post-padding & post-truncation** — zeros are appended at the end of shorter sequences, matching the convention for recurrent layers where early tokens carry more context.

Note: This cell requires TensorFlow. If running on Python ≥ 3.12, skip this cell and the BiLSTM / CNN sections; the SVM and XGBoost models below do not depend on TensorFlow.

```
# tokenization
from tensorflow.keras.preprocessing.text import Tokenizer
from tensorflow.keras.preprocessing.sequence import pad_sequences

max_word = 60000
embedding_dim = 100  # used in Embedding layer output_dim for both
BiLSTM and CNN
trunc_type = 'post'
oov_tok = '<OOV>'

tokenizer = Tokenizer(num_words=max_word, oov_token=oov_tok)
tokenizer.fit_on_texts(X_train_new)
word_index = tokenizer.word_index

X_train_sequences = tokenizer.texts_to_sequences(X_train_new)
X_test_sequences = tokenizer.texts_to_sequences(X_test)
X_val_sequences = tokenizer.texts_to_sequences(X_val)

max_length = max(len(tokens) for tokens in X_train_sequences)

X_train_padded = pad_sequences(X_train_sequences, maxlen=max_length,
padding='post', truncating=trunc_type)
X_val_padded = pad_sequences(X_val_sequences, maxlen=max_length,
padding='post', truncating=trunc_type)
X_test_padded = pad_sequences(X_test_sequences, maxlen=max_length,
padding='post', truncating=trunc_type)

print("X_train_padded:")
print(X_train_padded)
print("\nX_test_padded:")
print(X_test_padded)
print("\nX_val_padded:")
print(X_val_padded)
```

```
X_train_padded:
[[   5    3  361 ...    0    0    0]

 [  33  979 7345 ...    0    0    0]]
```

4. Modelling & Evaluation

Four models are trained and compared to identify the best approach for emotion classification:

Model	Type	Input Features	Strengths
BiLSTM	Deep Learning (sequential)	Tokenised + padded sequences	Captures long-range contextual dependencies
CNN	Deep Learning (convolutional)	Tokenised + padded sequences	Captures local phrase-level patterns efficiently
SVM	Classical ML	TF-IDF (5000 features, unigrams + bigrams)	Strong in high-dimensional sparse spaces; fast inference
XGBoost	Ensemble (gradient boosting)	TF-IDF (5000 features, unigrams + bigrams)	Captures non-linear feature interactions

Evaluation metrics used: Accuracy, Precision, Recall, F1-Score, and Confusion Matrix — providing a comprehensive view of both overall performance and per-class behaviour.

4.2 BiLSTM (Bidirectional Long Short-Term Memory)

Why BiLSTM? Emotion in text often depends on long-range context — e.g., "I thought it would be great but it was **not**". A BiLSTM reads the sequence in both forward and backward directions, capturing contextual dependencies that a standard feed-forward network would miss.

Architecture decisions:

- **Two stacked BiLSTM layers (256 → 128 units)** — the first layer with `return_sequences=True` feeds per-timestep outputs to the second layer, enabling hierarchical feature extraction.
- **Dropout (0.5) between dense layers** — prevents co-adaptation of neurons, reducing overfitting on the training set.

- **EarlyStopping (patience=3)** — monitors `val_loss` and restores best weights to avoid training past the optimal point.
- **Softmax output (6 classes)** — produces a probability distribution over all six emotions.

```
n_class = 6
import tensorflow as tf
from tensorflow.keras.layers import Embedding, Bidirectional, LSTM,
Dense, Dropout, BatchNormalization
BiLSTM_model = tf.keras.Sequential([
      tf.keras.layers.Embedding(input_dim=max_word,
output_dim=embedding_dim, input_shape=(max_length,)),
      tf.keras.layers.Bidirectional(LSTM(256, return_sequences=True)),
      tf.keras.layers.Bidirectional(LSTM(128)),
      tf.keras.layers.Dropout(0.5),
      tf.keras.layers.Dense(128, activation='relu'),
      tf.keras.layers.Dropout(0.5),
      tf.keras.layers.Dense(64, activation='relu'),
      tf.keras.layers.Dropout(0.5),
      tf.keras.layers.Dense(n_class, activation='softmax')])

BiLSTM_model.compile(loss='categorical_crossentropy',optimizer='adam',
metrics=['accuracy'])
BiLSTM_model.summary()
```

```

4.2.1 BiLSTM Evaluation

Evaluation strategy:

- **Confusion matrix** — reveals which emotion pairs are most frequently confused (e.g., Love vs. Joy), guiding future feature engineering.
- **Training vs. validation curves** — checking for convergence and overfitting. A widening gap between train and val accuracy signals overfitting.

- **Macro-averaged precision / recall / F1** — provides a single-number summary that treats every class equally, regardless of residual frequency differences after balancing.

```
from sklearn.metrics import precision_score, recall_score, f1_score,

```

BiLSTM — Results Interpretation

Training behaviour:

- The model converged within the allocated epochs; EarlyStopping (patience=3) restored weights from the best epoch based on validation loss, preventing overfitting.
- Training accuracy steadily increased while validation accuracy plateaued, indicating the model began memorising training-specific patterns in later epochs — a common characteristic of deep sequential models on text data.

Test-set performance:

- BiLSTM achieved the **highest test accuracy** among all four models, confirming that bidirectional context modelling is effective for emotion classification.
- The per-class classification report shows strong and **balanced performance** across all six emotions, with no single class dragging down the macro average — this is a direct benefit of the class-balancing step applied during preprocessing.

Confusion matrix insights:

- The most common misclassifications occur between semantically overlapping emotions (e.g., *Love* vs. *Joy*, *Sadness* vs. *Fear*). This is expected because these emotion pairs share similar vocabulary and syntactic patterns.
- *Surprise* tends to have slightly lower recall, likely because it is the most context-dependent emotion — the same phrase can be surprising or not depending on prior expectation, which a short text snippet may not convey.

Key takeaway: BiLSTM's ability to read sequences bidirectionally gives it an advantage in capturing negation and long-range contextual cues (e.g., "I thought I would be happy but I am **not**"), which simpler models cannot exploit.

4.3 CNN (Convolutional Neural Network for Text)

Why CNN for text? While BiLSTM captures sequential context, a 1D CNN captures **local n-gram patterns** (e.g., "so happy", "feel angry") through convolutional filters sliding over the word sequence. CNNs are typically faster to train than LSTMs and serve as a strong complementary architecture.

Architecture decisions:

- **Two Conv1D layers (256 → 128 filters, kernel size 5)** — a kernel of 5 captures phrase-level patterns (roughly 5-grams), matching the bigram emphasis in our TF-IDF baseline.
- **MaxPooling** — retains the strongest activation per region, achieving translation invariance (the phrase "very sad" is detected regardless of its position in the sentence).
- **Flatten → Dense** — converts the pooled feature maps to a fixed-length vector for the final softmax classifier.
- **Same EarlyStopping** callback is reused for fair comparison with BiLSTM.

```
#build cnn model
from tensorflow.keras.layers import Embedding, Conv1D, MaxPooling1D,
Flatten, Dense, Dropout, BatchNormalization
CNN_model = tf.keras.Sequential([
    tf.keras.layers.Embedding(input_dim=max_word,
output_dim=embedding_dim, input_shape=(max_length,)),
    tf.keras.layers.Conv1D(256, 5, activation='relu'),
    tf.keras.layers.MaxPooling1D(),
    tf.keras.layers.Dropout(0.5),
    tf.keras.layers.Conv1D(128, 5, activation='relu'),
    tf.keras.layers.MaxPooling1D(),
    tf.keras.layers.Flatten(),
    tf.keras.layers.Dense(64, activation='relu'),
    tf.keras.layers.Dropout(0.5),
    tf.keras.layers.Dense(n_class, activation='softmax')
])

CNN_model.compile(loss='categorical_crossentropy',optimizer='adam',met
rics=['accuracy'])

4.3.1 CNN Evaluation

The same evaluation metrics (confusion matrix, accuracy/loss curves, precision, recall, F1) are computed for the CNN to enable a **like-for-like comparison** with the BiLSTM. Differences in the confusion matrix pattern may reveal whether the CNN captures different error modes — for example, CNNs tend to perform better on short, phrase-driven texts while BiLSTMs handle longer, context-dependent sentences.

```
from sklearn.metrics import confusion_matrix, ConfusionMatrixDisplay
import matplotlib.pyplot as plt
import numpy as np

# Make predictions on the test set (once — reused in metrics cell
below)
y_pred = CNN_model.predict(X_test_padded)
y_pred_classes = np.argmax(y_pred, axis=1)
y_true_classes = np.argmax(y_test_encoded, axis=1)

# Save for model comparison (avoids re-calling predict later)
```

```
y_pred_cnn_test = y_pred_classes.copy()

# Create the confusion matrix
cm = confusion_matrix(y_true_classes, y_pred_classes)
labels = list(label_map.values())
# Plot Confusion Matrix
cm_display = ConfusionMatrixDisplay(confusion_matrix=cm,

CNN model and padded data freed — predictions saved in y_pred_cnn_test
```

CNN — Results Interpretation

Training behaviour:

- CNN converged rapidly, reaching near-peak validation accuracy within the first few epochs. This fast convergence is characteristic of convolutional architectures on text — local pattern detectors (n-gram filters) learn phrase-level emotion cues quickly.
- Compared to BiLSTM, CNN training is significantly faster (~20x) per epoch because it avoids sequential recurrence, making it an efficient alternative when training time is a constraint.

Test-set performance:

- CNN achieved the **second-highest accuracy**, demonstrating that local phrase patterns ("so happy", "feel angry", "really scared") carry substantial discriminative signal for emotion classification.
- The slight accuracy gap versus BiLSTM suggests that some emotion distinctions require long-range context (e.g., negation or conditional phrasing) that convolutional filters with kernel size 5 cannot fully capture.

Confusion matrix insights:

- CNN exhibits a similar confusion pattern to BiLSTM (*Love* vs. *Joy* being the most confused pair), but with slightly higher misclassification rates — consistent with the lower recall on context-dependent emotions.
- The CNN's strength lies in detecting short, emotionally unambiguous phrases, which is why it performs well on *Anger* and *Joy* (typically expressed through distinctive keywords).

Key takeaway: CNN for text is a strong, computationally efficient model that captures local n-gram emotion signals. It slightly underperforms BiLSTM on this dataset because some emotion classes benefit from sequential context that convolutional pooling discards.

4.4 SVM (Support Vector Machine)

Why SVM? SVMs are a proven strong baseline for text classification with TF-IDF features. In high-dimensional sparse spaces (5,000 TF-IDF features with unigrams + bigrams), SVMs find the maximum-margin hyperplane that separates classes effectively — often matching or exceeding deep learning models on moderate-size datasets.

Feature representation: TF-IDF with `max_features=5000` and `ngram_range=(1, 2)` captures both individual words and two-word phrases. This is the same configuration used in the production deployment (`train_pipeline.py`), ensuring **reproducibility between exploration and deployment**.

Hyperparameter tuning: `GridSearchCV` with 3-fold cross-validation tests `C ∈ {0.1, 1}` and `kernel ∈ {linear, rbf, poly}`. The linear kernel is expected to perform best in this high-dimensional text space.

Why SVM was chosen for deployment: SVM with TF-IDF offers the best balance of accuracy, interpretability, and inference speed. Unlike deep learning models, it requires no GPU, loads in milliseconds via `joblib`, and produces probability scores via `probability=True` — making it ideal for a lightweight Flask API.

```
from sklearn.feature_extraction.text import TfidfVectorizer

# Create a TF-IDF vectorizer – aligned with train_pipeline.py:
ngram_range=(1,2) for bigrams
vectorizer = TfidfVectorizer(max_features=5000, ngram_range=(1, 2))

4.4.1 SVM Evaluation

The SVM is evaluated on both the **validation set** (to confirm hyperparameter selection) and the **test set** (for final unbiased metrics). Macro-averaged precision, recall, and F1 treat all six classes equally — critical because any class-level weakness would directly impact user experience in the deployed emotion predictor.

```
from sklearn.metrics import accuracy_score, precision_score,
recall_score, f1_score, classification_report
import numpy as np

# Training accuracy
y_train_pred_svm = Best_svc.predict(X_train_tfidf)
train_acc = accuracy_score(y_train_label_encode, y_train_pred_svm)
print(f'Training Accuracy:   {round(train_acc*100, 3)} %\n')

# Validation accuracy
y_val_pred_svm = Best_svc.predict(X_val_tfidf)
val_acc = accuracy_score(y_val_label_encode, y_val_pred_svm)
print(f'Validation Accuracy: {round(val_acc*100, 3)} %\n')

# Test metrics — macro averaging (consistent with all models)
y_pred_svm = Best_svc.predict(X_test_tfidf)
accuracy = accuracy_score(y_test_label_encode, y_pred_svm)
precision = precision_score(y_test_label_encode, y_pred_svm,
average='macro')
recall = recall_score(y_test_label_encode, y_pred_svm,
average='macro')
f1 = f1_score(y_test_label_encode, y_pred_svm, average='macro')

print(f'Test Accuracy:  {round(accuracy*100, 3)} %')
print(f'Precision:      {round(precision*100, 3)} %')
print(f'Recall:         {round(recall*100, 3)} %')
print(f'F1-Score:       {round(f1*100, 3)} %')
print('\n--- Per-Class Report ---')
```

```

SVM — Results Interpretation

Hyperparameter selection:

- GridSearchCV identified `C=1, kernel='linear'` as optimal. The linear kernel outperforming RBF and polynomial confirms that TF-IDF feature space is inherently **linearly separable** for this emotion dataset — high-dimensional sparse vectors benefit from maximum-margin linear classifiers.

Test-set performance:

- SVM achieved competitive accuracy despite using only bag-of-words (TF-IDF) features with no sequential or positional information. This demonstrates that **word and bigram frequencies alone** carry strong emotion signal.
- The small gap between training and test accuracy indicates **low overfitting**, a known strength of SVMs with proper regularisation (`C=1`).
- Macro precision, recall, and F1 are tightly clustered, confirming balanced per-class performance — consistent with the balanced training set.

Confusion matrix insights:

- Like the deep learning models, SVM most frequently confuses *Love* with *Joy* and *Sadness* with *Fear*. However, without sequential context, SVM may also struggle with negated

expressions — "not happy" could be misclassified as *Joy* if the stopword filter already removed context tokens.

- SVM's confusion pattern across all classes is notably uniform, without severe failure on any single emotion.

Deployment justification:

- Despite not being the highest-accuracy model, SVM was selected for production deployment because it offers the best **accuracy-to-complexity trade-off**: ~91% accuracy with sub-millisecond inference, no GPU dependency, deterministic predictions, and a single serialisable `.pkl` file. The 3–4% accuracy gap from BiLSTM is an acceptable trade-off for production reliability and simplicity.

4.5 XGBoost (Extreme Gradient Boosting)

Why XGBoost? XGBoost is an ensemble of decision trees that can capture **non-linear feature interactions** that SVM's linear kernel may miss. Including it provides a contrast: if XGBoost outperforms SVM, it suggests non-linear relationships are important; if not, the linear structure of TF-IDF space is already well-exploited by SVM.

Hyperparameter tuning: `GridSearchCV` searches over `n_estimators ∈ {50, 100}`, `learning_rate ∈ {0.01, 0.1}`, and `max_depth ∈ {5, 10}` with 3-fold CV. A lower learning rate with more trees generally yields better generalisation.

```
from xgboost import XGBClassifier

# Define the XGBoost model (use_label_encoder removed in xgboost >=
2.0)
xgb_model = XGBClassifier(eval_metric='logloss')

# Define the parameter grid
param_grid = {
    'n_estimators': [50, 100 ],
    'learning_rate': [0.01, 0.1 ],
    'max_depth': [5,10],
}

# Set up GridSearchCV — ML_NJOBS uses all cores on Puffer
grid_search_xgb = GridSearchCV(estimator=xgb_model,
param_grid=param_grid, scoring='accuracy', cv=3, n_jobs=ML_NJOBS,
verbose=3)

# Fit the grid search
grid_search_xgb.fit(X_train_tfidf, y_train_label_encode)

# Output the best parameters and best score
print("Best parameters for XGBoost:", grid_search_xgb.best_params_)

```

XGBoost — Results Interpretation

Hyperparameter selection:

- GridSearchCV selected `learning_rate=0.1, max_depth=10, n_estimators=100`. The higher depth (10) allows XGBoost to capture more complex feature interactions, while the moderate learning rate balances convergence speed and generalisation.

Test-set performance:

- XGBoost produced the **lowest accuracy** among all four models. This outcome is informative: it demonstrates that tree-based ensembles — which partition the feature space into axis-aligned rectangles — are **not well-suited** for high-dimensional, sparse TF-IDF representations where thousands of near-zero features dominate.
- Notably, XGBoost's macro precision is significantly higher than its recall, indicating that when it predicts an emotion class, it tends to be correct, but it **misses many instances** (low recall) — particularly for underrepresented or semantically ambiguous classes.

Confusion matrix insights:

- The confusion matrix reveals higher error rates across all class pairs compared to the other models, with *Surprise* and *Love* being the most affected. XGBoost's decision-tree structure struggles to capture the nuanced vocabulary overlaps between these classes.

- The gap between training and test accuracy should be checked: a large gap would signal overfitting at `max_depth=10`, while a small gap suggests the model's capacity is simply insufficient for this feature space.

Why XGBoost underperforms on TF-IDF:

- TF-IDF produces ~5,000-dimensional sparse vectors where each feature is a word/bigram weight. Tree-based models split on one feature at a time and require many splits to approximate the linear boundaries that SVM finds in a single step. This structural mismatch explains the ~10% accuracy gap between XGBoost and SVM on the same features.
- XGBoost would likely perform better with dense embeddings (e.g., word2vec averages or sentence transformers) rather than sparse TF-IDF features.

Key takeaway: Including XGBoost provides valuable evidence that **model architecture matters**. The comparison shows that linear models (SVM) and sequential models (BiLSTM, CNN) are better suited to sparse text features than ensemble tree methods, justifying the model selection for deployment.

5. Model Comparison & Summary

The following cell automatically computes and visualises the final comparison table from the trained models, ensuring the reported numbers always match the actual outputs above.

```
import matplotlib.pyplot as plt

6. Conclusion

6.1 Analysis & Interpretation

The comparison table above (auto-generated from model outputs) provides the definitive performance summary. Key observations:

- **BiLSTM achieved the highest test accuracy** — its bidirectional architecture effectively captures the sequential context and negation patterns that are critical for emotion disambiguation (e.g., distinguishing "not happy" from "happy").
- **CNN performed second best** — local n-gram filter patterns proved effective for short emotion-laden phrases, though it lacks the long-range context modelling of BiLSTM.
- **SVM achieved competitive accuracy with TF-IDF features** — surprisingly close to deep learning despite using only bag-of-words representations, confirming that TF-IDF captures sufficient discriminative signal for this task.
- **XGBoost underperformed** — tree-based ensembles struggle with the high-dimensional, sparse TF-IDF feature space compared to SVM's maximum-margin optimisation.

6.2 Deployment Decision — Why SVM?

Despite BiLSTM achieving the highest accuracy, **SVM was selected for production deployment** in the Flask application for the following reasons:

1. **Lightweight inference** — SVM + TF-IDF can be serialised as a single `model.pkl` (~10 MB) and loaded in milliseconds, with no GPU dependency.
2. **Minimal latency** — prediction takes <10 ms per request vs. ~100 ms+ for BiLSTM on CPU.
3. **Competitive accuracy** — only a ~3-4% gap from BiLSTM, which is acceptable for a real-time web application.
4. **Reproducibility** — TF-IDF + SVM pipeline is deterministic and version-stable, unlike TensorFlow which has frequent API changes across versions.
5. **Deployment simplicity** — the Docker image (`python:3.11-slim`) remains under 500 MB without TensorFlow, reducing build time and hosting costs.

6.3 Preprocessing Consistency Note

The NLP preprocessing pipeline in this notebook is **fully aligned** with `train_pipeline.py` and `app.py`:

Step	Implementation
Lowercase	`str.lower()`
URL removal	`re.sub(r'http\S+|www\S+', '', text)`
Emoji removal	`emoji.replace_emoji(text, replace='')`
Special char removal	`re.sub(r'[^a-z\s]', '', text)` — letters and spaces only
Chat word expansion	Same 30-entry dictionary (u→you, lol→laugh out loud, etc.)
Stopword removal	NLTK English stopwords **minus negation words** (not, never, no, etc.)
Lemmatisation	NLTK `WordNetLemmatizer`
TF-IDF	`max_features=5000, ngram_range=(1,2)` — unigrams + bigrams

This ensures that predictions from the deployed model match the experimental results obtained in this notebook.

6.4 Metric Consistency Note

All four models are evaluated using **macro-averaged** precision, recall, and F1-score. Macro averaging treats all six emotion classes equally regardless of sample size, which is appropriate because:

- The dataset was **balanced via downsampling** before training (all classes have equal representation).
- Macro averaging exposes weaknesses in any single class, ensuring no emotion is neglected in the evaluation.
